## ABSTRACT

**Title of Thesis:** REAL-TIME GPU SURFACE CURVATURE ESTIMATION

Wesley Griffin, Master of Science, 2010

**Thesis directed by:** Dr. Marc Olano, Associate Professor  
Department of Computer Science and  
Electrical Engineering

Surface curvature is used in a number of areas in computer graphics including mesh simplification, surface modeling and denoising, feature detection, and non-photorealistic line drawing techniques. Most applications must estimate surface curvature, due to the use of discrete models such as triangular meshes. Until recently, curvature estimation has been limited to CPU algorithms, forcing object geometry to reside in main memory. More computational work is being done directly on the GPU, and it is increasingly common for object geometry to only exist in GPU memory. Examples include vertex skinned animations, isosurfaces from GPU-based surface reconstruction algorithms, or triangular meshes generated by hardware tessellation units.

All of these types of geometry can be large in size and transferring the data to the CPU is cost prohibitive in interactive applications, especially if the mesh changes every frame. Thus, for static models, CPU algorithms for curvature estimation are a reasonable choice, but for models where the object geometry only resides on the GPU, CPU algorithms limit performance. I introduce a GPU algorithm for estimating curvature in real-time on arbitrary triangular meshes residing in GPU memory. I test my algorithm in a line drawing system with a vertex-skinned animation system and a GPU-based isosurface extraction system.

## ACKNOWLEDGMENTS

I would first like to thank Kim who encouraged me to pursue my desires and for her love and support. I would also like to thank Scott for convincing me to attend graduate school.

I would like to thank my advisor, Dr. Marc Olano, for his feedback, suggestions and help. I also must thank my committee - their comments certainly improved this work. Many thanks to the VANGOGH lab for discussion and proof-reading, especially Kish, for tirelessly working through concepts with me.

Thanks to Szymon Rusinkiewicz for making the trimesh2 library publicly available (2009). The animated models are from the Skinning Mesh Animations project (James & Twigg 2009) and the volumes are from the Volume Library (Röttger 2010).

## LIST OF FIGURES

1.1	Occluding and suggestive contours on a tone-shaded isosurface reconstruction of a hydrogen atom volume. . . . .	6
2.1	The tangent plane, $T_{\mathbf{p}}(\mathbf{M})$ , to a surface $\mathbf{M}$ at two points $\mathbf{p}$ and $\mathbf{p}'$ . Curvature describes how the tangent plane changes from $\mathbf{p}$ to $\mathbf{p}'$ . . . . .	8
2.2	Estimating curvature using the directional derivatives of normal vectors (See Equation 2.7). The normal vectors at each vertex are shown in green, while the directions $\mathbf{u}$ and $\mathbf{v}$ are shown in blue. . . . .	10
2.3	Directions and values of principal curvature on a torus. Blue lines show the principal directions of minimum curvature and brown lines show the principal directions of maximum curvature. On the legend, $k_1$ is maximum curvature and $k_2$ is minimum curvature. . . . .	11
2.4	The modern programmable graphics pipeline. The shaded stages are programmable, while the non-shaded stages are highly configurable. .	14
3.1	The left is a triangle containing vertex $v_2$ with adjacent vertices. The right is a one-ring neighborhood of faces around vertex $v_2$ . Notice that adjacency information does not allow access to vertices $v_6$ and $v_7$ in the one-ring. . . . .	22

3.2	The contribution of the one-ring neighborhood of a vertex is averaged by blending into a single pixel of a render target. A single vertex with the one-ring of faces is indicated by the dashed circle. The same vertex from each face is mapped as a point primitive to a single pixel of a render target. The blue lines show a complete one-ring, while the red and green lines show how other vertices could be mapped. . . . .	23
3.3	Flowchart of the parallel algorithm. The outer grey outline encloses the main algorithm. See Section 3.5 for further discussion. . . . .	25
3.4	Two close-up frames of a vertex-blended animation showing principal curvatures and principal directions of minimum curvature (blue lines).	28
4.1	Frame times and relative speedup for the non-animated models at $1280 \times 1024$ resolution. The results are for just curvature estimation (no line drawing). Red is a multi-threaded CPU algorithm, blue is an NVIDIA GeForce 9800GT, and green is an NVIDIA Quadro FX5800. . . .	31
4.2	Scaled absolute error in the principal directions and principal curvatures on the Quadro FX5800 compared to a CPU estimation ground truth. . . . .	36
4.3	Scaled absolute error in the estimated derivative of principal curvature on the Quadro FX5800 compared to a CPU estimation ground truth. .	36
4.4	Scaled absolute error in the estimated Gauss and Mean Curvatures on the Quadro FX5800 compared to a CPU estimation ground truth. . . .	37
4.5	A coloring of principal curvatures as described in Section 4.3. . . . .	39
4.6	The bucky ball volume with two different iso values and principal curvatures. The marching cubes algorithm takes 40 ms to reconstruct the surface, and the curvature algorithm takes 1.3 ms to estimate curvature.	39

4.7	The heptoroid model with 286,678 vertices. The top left and middle images show occluding and suggestive contours with lambertian shading, while the bottom left and right images show values of principal curvature. . . . .	40
4.8	A sequence of frames from the camel model. The middle frame shows principal directions and the last frame shows principal values of curvatures. . . . .	41
4.9	The animated horse model. The first two pictures show just the principal curvatures. The last two pictures show the principal directions of minimum (blue lines) and maximum (brown lines) curvature. . . . .	41
4.10	Principal curvatures on the high-quality elephant model. . . . .	41
4.11	Looking into an extracted surface of the bucky ball volume with tone shading. . . . .	41
4.12	The orange volume with over 1.5B vertices. Curvature is estimated in 32.1 ms (31 fps) on this surface that is computed in 928 ms. . . . .	42

## LIST OF TABLES

3.1	Operations that can be performed in parallel grouped by their input. The output is listed as well as whether it should be averaged or summed across the one-ring neighborhood of a vertex. . . . .	18
3.2	Average valence of the models. . . . .	19
4.1	Memory usage and CPU performance at $1280 \times 1024$ resolution. <b>RAM</b> is just the render targets and geometry buffers, while <b>(Total)</b> includes a super-sampled depth buffer and other shared overhead. <b>Algorithm</b> refers to a multi-threaded benchmark CPU algorithm. . . . .	32
4.2	Frame times on an GeForce 9800GT with 512MB of RAM. <b>Procedural</b> refers to drawing procedurally textured lines. <b>Basic</b> refers to drawing non-textured line primitives. <b>Algorithm</b> refers to just the algorithm (no line drawing). The (x) columns show the relative speedup over the CPU algorithm. . . . .	33
4.3	Frame times on an NVIDIA Quadro FX5800 with 4096MB of RAM. <b>Procedural</b> refers to drawing procedurally textured lines. <b>Basic</b> refers to drawing non-textured line primitives. <b>Algorithm</b> refers to just the algorithm (no line drawing). The (x) columns show the relative speedup over the CPU algorithm. . . . .	33

4.4	Frame times for different volumes at $1280 \times 1024$ resolution on the NVIDIA Quadro FX5800. <b>I-V</b> is the iso value of the surface and <b>E-T</b> is the elapsed time to extract the surface. <b>Lines</b> refers to drawing non-textured line primitives. <b>Algorithm</b> refers to just the algorithm (no line drawing). . . . .	34
4.5	Maximum absolute error in the curvature attributes over the torus. . .	35

## INTRODUCTION

Surface curvature is used in a number of areas in computer graphics including texture synthesis and shape representation, mesh simplification, surface modeling, and artistic line drawing techniques. All of these techniques, which I describe next, operate on a discrete polygonal representation (almost always triangular polygons) of a continuous surface, called a mesh or model.

Texture synthesis is a technique to generate a texture that seamlessly covers a mesh from a small exemplar texture. Gorla et al. (2003) present a technique that would use principal directions of curvature, provided reliable estimates were available, to drive texture synthesis and affect shape recognition. Mesh simplification attempts to create a new mesh that has fewer triangles than an existing mesh, but that still resembles the approximated surface. An optimal approximation to mesh simplification relies on surface curvature (Heckbert & Garland 1999). Surface modeling, on the other hand, creates a smooth mesh from a specified set of geometric constraints, which include surface curvature. Moreton and Séquin's (1992) algorithm minimizes the variation of curvature in evaluating the smooth mesh.

### **1.1 Artistic Line Drawing**

Most computer graphics image generation is concerned with generating realistic images. Artistic line drawing techniques (Section 2.3) instead attempt to generate images that mimic an artistic style, such as pen-and-ink drawings or use hatching to convey lighting and shading in generated images. Artistic techniques

are more commonly referred to as non-photorealistic rendering (NPR).

When drawing lines, there are a number of lines, or contours, that can be drawn, many of which are based on curvature. The simplest form of contours, occluding contours, do not depend on curvature. Occluding contours are the set of points where the surface normal is perpendicular to the viewing direction. When drawn, these contours form a silhouette around the mesh. Suggestive contours (DeCarlo et al. 2003) use the derivative of curvature to draw “almost contours”, which would be contours if the view was shifted slightly. Other types of contours based on curvature are ridge and valley contours. These contours are the set of points of local minimum or maximum curvature. Kolomenkin, Shinshoni, and Tal (2008) use the gradient of curvature to locate the points of inflection between ridges and valleys. Demarcating curves are the set of points where the inflection is strongest.

Judd, Durand, and Adelson (2007) define view-dependent curvature by projecting curvature onto the viewing plane where the image is rendered (screen space). They then define apparent ridges as the set of points of local minimum or maximum view-dependent principal curvature.

## 1.2 Curvature

Intuitively, curvature describes how a curve turns as a particle moves along the curve over time. On a surface, normal curvature (Section 2.1) describes how a surface bends as a particle moves around the surface over time. Curvature, in general, is defined on continuous surfaces. In computer graphics, however, only a discrete polygonal representation of the continuous surface exists and must be estimated.

Curvature estimation algorithms (Section 2.2) have traditionally been implemented on general purpose CPUs, thereby forcing object geometry to reside in

main memory. This requirement was not considered a limitation as geometry always resided in main memory. However, more computational work is being performed directly on the graphics processing unit (GPU) and it is not unreasonable for object geometry to only exist in GPU memory. I describe three cases where geometry only exists on the GPU in the following section.

For static models, curvature only needs to be estimated once, so CPU algorithms are a reasonable choice, but for deforming models, curvature must be estimated every time the model changes. Estimating curvature every frame on the CPU is expensive, especially if the geometry exists on the GPU and must be transferred to the CPU. Algorithms do exist to estimate curvature in real-time on deforming models. These methods either work in image-space (Kim et al. 2008) or require a pre-processing step to learn the curvature function on a training data set (Kalogerakis et al. 2009). While both techniques can be useful, the ability to estimate curvature in object-space and without pre-processing training data would provide much greater flexibility.

### **1.3 Computed Object Geometry**

Below I present three cases where object geometry only exists in GPU memory: vertex skinned animations used in video games, isosurfaces from GPU-based surface reconstruction algorithms, and triangular meshes generated by hardware tessellation units. In these situations, transferring the geometry off the GPU to CPU memory to estimate curvature would be cost prohibitive.

Video games are starting to use non-photorealistic rendering techniques for a more distinctive look (Mitchell, Francke, & Eng 2007; gearbox software 2009). In most cases, these rendering techniques are applied to animated models that move dynamically based on interaction with the user. Thus, these animated models will change every frame and must be rendered in real-time. Video games

often use vertex-blended animations, also called vertex skinning, (Section 2.4) to animate the models each frame. With vertex skinning, an initial pose mesh for each model is transferred to the GPU just once. This pose mesh is then modified each frame using blended transformation matrices to create an deformed mesh corresponding to the animation for that frame. After skinning, the transformed mesh only exists in GPU memory. Given the strict real-time requirements of video games, transferring the vertex-blended animated models to the CPU to estimate curvature is too costly.

GPU Computing, or General Purpose Computing on Graphics Hardware, exploits the massively parallel processing capability of modern graphics cards by executing general purpose code on GPUs. This trend has increased the performance of scientific simulation computations and visualizations. Typically, large data sets are uploaded to the GPU and then a data-parallel algorithm is executed over the data. Often, when working with volumetric data sets, these applications need to visualize a surface re-constructed from the data set. I review surface reconstruction in Section 2.5. As GPU memory capacity increases (workstation-class cards currently have 4GB of RAM) GPUs can store higher resolution data sets (greater numbers of polygons or larger dimension volumes) or more time steps of time-varying data. Once the data set is uploaded to the GPU for computation, transferring the data back to the CPU for surface reconstruction is costly. In situations where an isosurface needs to be computed every time step (for time-varying data) or recomputed interactively, reconstruction on a GPU can offer improved performance for visualizing data in real-time. I describe a GPU implementation of the marching cubes algorithm (Section 2.5) for surface reconstruction in Section 3.5.1. After reconstruction, the surface only exists in GPU memory and transferring the geometry to the CPU to estimate curvature would be very expensive.

Tessellation is a process of refining a low-detail mesh (i.e. a mesh with a small number of vertices) into a mesh that contains detailed geometric features. Hardware tessellation units have existed for some time (Vlachos et al. 2001), but with the introduction of the latest version of Microsoft’s Graphics API, DirectX 11 (Microsoft 2010), hardware-based tessellation is now part of a graphics programming interface specification. For hardware tessellation, a low-detail mesh is uploaded to the GPU and then tessellated, or subdivided, by the GPU. Video games can benefit from hardware-based tessellation to enhance low-detail models in hardware. In these applications a potentially large triangular mesh will likely be generated every frame and only exist in GPU memory.

#### **1.4 Contributions**

Estimating curvature with a CPU algorithm is a reasonable choice for static models, but in the case of deforming models or where the object geometry only exists in GPU memory, estimating curvature on the CPU is too costly. Therefore, I introduce a GPU algorithm for estimating curvature that works in object-space and does not require any pre-processing or training data. Given an arbitrary triangular mesh in GPU memory, the algorithm computes principal curvatures, principal directions of curvature, the derivative of principal curvatures, and Gauss and Mean curvatures at each vertex of the mesh in real-time. Since the algorithm runs completely on the GPU and works on triangular meshes, it can be easily adapted to existing rendering systems.

To demonstrate my algorithm I implemented a vertex-blending animation system and a GPU-based isosurface extraction system, both of which use curvature to extract and stroke occluding and suggestive contours on input data. My algorithm runs in 41.9 ms (23 frames per second) on a model of 286,678 vertices while estimating curvature every frame on the model. This is a speedup of 7.6

over an 8-core multi-threaded CPU implementation used as a benchmark. My algorithm also runs in 21.1 ms (31 frames per second) on an isosurface reconstruction containing 1,558,788 vertices while estimating curvature every frame. My system can recompute the isosurface interactively, and computing this specific isosurface took 928 ms.

The specific contributions of this work are:

- A real-time GPU algorithm that computes principal curvatures, principal directions of curvature, and the derivative of curvature.
- A marching cubes CUDA implementation that creates fused vertices.

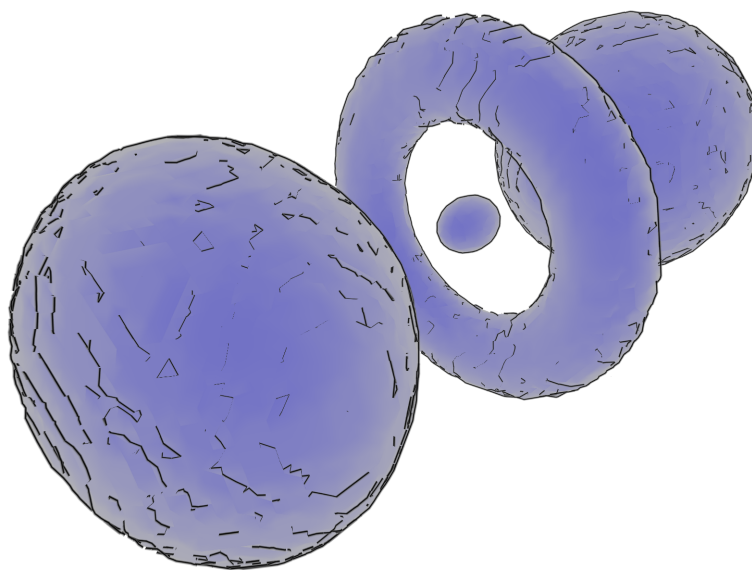

FIGURE 1.1: Occluding and suggestive contours on a tone-shaded isosurface reconstruction of a hydrogen atom volume.

The rest of this document is organized as follows: I discuss background and related work in Chapter 2, describe the algorithm in detail in Chapter 3, and present my results in Chapter 4.

## BACKGROUND AND RELATED WORK

My system combines a number of components: curvature and curvature estimation, line drawing, vertex-blended animation, and isosurface reconstruction.

### 2.1 Curvature

Below, I briefly discuss curvature and refer the reader to O’Neill (2006) for more detail and relevant proofs of theorems.

At a point  $\mathbf{p}$  on an oriented surface  $\mathbf{M}$ , curvature describes how the tangent plane,  $\mathbf{T}_{\mathbf{p}}(\mathbf{M})$ , changes in different directions around  $\mathbf{p}$  on  $\mathbf{M}$ . An oriented surface is a surface where a consistent direction for the normal vector at each point has been chosen. For example, on a sphere, normals can point either inwards or outwards, an oriented sphere is a sphere where the normals have been chosen to point only in one direction. Surface normals are considered first-order structure of smooth surfaces: at a point  $\mathbf{p}$ , a normal vector  $\mathbf{N}_{\mathbf{p}}$  defines a tangent plane  $\mathbf{T}_{\mathbf{p}}(\mathbf{M})$  to a surface  $\mathbf{M}$ . Figure 2.1 illustrates the tangent plane changing from one point to another.

Curvature is typically defined in terms of the shape operator  $S_{\mathbf{p}}(\mathbf{u})$ , which is the rate of change of a unit normal vector field,  $U$  in the direction  $\mathbf{u}$ , where  $\mathbf{u}$  is a tangent vector to  $\mathbf{M}$  at some point  $\mathbf{p}$ :

$$(2.1) \quad S_{\mathbf{p}}(\mathbf{u}) = -\nabla_{\mathbf{u}} U.$$

The shape operator is a symmetric linear operator, such that:

$$(2.2) \quad S(\mathbf{u}) \cdot \mathbf{v} = S(\mathbf{v}) \cdot \mathbf{u}$$

FIGURE 2.1: The tangent plane,  $T_p(\mathbf{M})$ , to a surface  $\mathbf{M}$  at two points  $\mathbf{p}$  and  $\mathbf{p}'$ . Curvature describes how the tangent plane changes from  $\mathbf{p}$  to  $\mathbf{p}'$ .

for any pair of tangent vectors  $\mathbf{u}, \mathbf{v}$  to  $\mathbf{M}$  at  $\mathbf{p}$  (O'Neill 2006).

Since the shape operator is a symmetric linear operator, it can be written as a  $2 \times 2$  symmetric matrix,  $S$ , for each point  $\mathbf{p}$  given an orthonormal basis at  $\mathbf{p}$ . This symmetric matrix has real eigenvalues,  $\lambda_1$  and  $\lambda_2$  and eigenvectors,  $\mathbf{v}_1$  and  $\mathbf{v}_2$ . The eigenvalues are called Principal Curvatures and the eigenvectors are called Principal Directions.

Gauss Curvature,  $K$ , and Mean Curvature,  $H$ , can then be defined using the eigenvalues:

$$(2.3) \quad K(\mathbf{p}) = \lambda_1 \lambda_2 = \det S$$

$$(2.4) \quad H(\mathbf{p}) = \frac{1}{2}(\lambda_1 + \lambda_2) = \frac{1}{2} \text{trace } S$$

Another way to describe curvature is normal curvature,  $k(\mathbf{u})$ . There is a theorem that relates normal curvature to the shape operator:

$$(2.5) \quad k(\mathbf{u}) = S(\mathbf{u}) \cdot \mathbf{u},$$

where  $\mathbf{u}$  is a tangent vector to  $\mathbf{M}$  at a point  $\mathbf{p}$ . The maximum and minimum values of  $k(\mathbf{u})$  at  $\mathbf{p}$  are called principal curvatures,  $k_1$  and  $k_2$  and the directions in which

the maximum and minimum occur are called principal directions. Normal curvature is second-order structure and effectively defines a quadric approximation to  $\mathbf{M}$  at  $\mathbf{p}$ .

Traditionally, the second fundamental form is used to describe curvature, and it can be defined in terms of the shape operator:

$$(2.6) \quad \mathbf{II}(\mathbf{u}, \mathbf{v}) = S(\mathbf{u}) \cdot \mathbf{v}.$$

$\mathbf{II}$  is also called the curvature tensor and can be written using the directional derivatives of normals (Rusinkiewicz 2004):

$$(2.7) \quad \mathbf{II}(\mathbf{u}, \mathbf{v}) = \begin{pmatrix} D_{\mathbf{u}}n & D_{\mathbf{v}}n \end{pmatrix} = \begin{pmatrix} \frac{\partial n}{\partial \mathbf{u}} \cdot \mathbf{u} & \frac{\partial n}{\partial \mathbf{v}} \cdot \mathbf{u} \\ \frac{\partial n}{\partial \mathbf{u}} \cdot \mathbf{v} & \frac{\partial n}{\partial \mathbf{v}} \cdot \mathbf{v} \end{pmatrix}.$$

## 2.2 Curvature Estimation

On a discrete surface curvature must be estimated. There has been substantial work in estimating surface curvature (Taubin 1995; Petitjean 2002; Goldfeather & Interrante 2004; Rusinkiewicz 2004; Tong & Tang 2005). Gatzke and Grimm (2006) divide the algorithms into three groups: surface fitting methods, discrete methods that approximate curvature directly, and discrete methods that estimate the curvature tensor (Equation 2.6). In the group that estimates the curvature tensor, Rusinkiewicz (2004) and Theisel et al. (2004) estimate curvature on a triangular mesh at each vertex by averaging the per-face curvature (calculated using surface normals and Equation 2.7) of each adjacent face to the vertex (Figure 2.2). These algorithms have been limited to running on the CPU where the algorithm can access faces adjacent to a vertex (the one-ring neighborhood of the vertex).

Figure 2.3 shows directions and values of principal curvature estimated on a triangular mesh representing a torus. The blue lines are directions of minimum

FIGURE 2.2: Estimating curvature using the directional derivatives of normal vectors (See Equation 2.7). The normal vectors at each vertex are shown in green, while the directions  $\mathbf{u}$  and  $\mathbf{v}$  are shown in blue.

curvature and, as expected on a torus, are flow around the torus, all in the same direction. Likewise, the brown lines, which are directions of maximum curvature, flow “up and down” the torus in the expected direction of maximum curvature. The coloring legend helps to visually understand how the torus is curving at specific points. For the torus, the red areas are “elliptic”, which is where the surface is completely curving away from the surface normal at each point. The green areas are “hyperbolic”, which is where the surface is curving away from the normal in one direction and curving towards the normal in another direction. The red and green areas are separated by a thin yellow area along the “top” and “bottom” of the torus, where the surface is still curving in one direction, but flat in another direction.

Recently Kim et al. (2008) introduced an image-based technique that estimates curvature in real-time on the GPU. Their method traces rays based on the normals at a point to estimate the direction of curvature.

FIGURE 2.3: Directions and values of principal curvature on a torus. Blue lines show the principal directions of minimum curvature and brown lines show the principal directions of maximum curvature. On the legend,  $k_1$  is maximum curvature and  $k_2$  is minimum curvature.

Kalogerakis et al. (2009) also present a real-time method for estimating curvature specifically on animated models. Their method requires a mesh that is deforming according to some provided parameterization, such as per-frame transformation matrices, as described in Section 2.4. They use a pre-processing step that learns a mapping from the animation parameters to curvature attributes. This pre-processing step must estimate curvature for each value of the parameterization, thus, for a vertex-skinned model, curvature will be estimated for every frame. Once the mapping has been created, their algorithm predicts curvature attributes in real-time given an unseen set of animation parameters.

One drawback of this approach is that the input data set must have a parameterization that can be used for the learning algorithm. Also, the method is limited to the range of motions expressed in the animation parameter training data set. If the training data does not cover motions that are part of the real-time input data, the method will not be able to accurately predict the curvature on those motions.

While the methods by Kim et al. (2008) and Kalogerakis et al. (2009) can be useful, the ability to estimate curvature in object-space, without pre-processing,

and on unseen motions would provide greater flexibility in using curvature.

### 2.3 Line Drawing

Line drawing algorithms can be subdivided into two classes: image-based and object-based. Image-based techniques rasterize the scene, sometimes multiple times, and use image processing techniques to find surface properties and feature lines which are then drawn into the scene. The algorithms must estimate curvature on the objects in the image. Image-based algorithms are easier to implement than object-based methods but have some deficiencies. First, the algorithm will have to handle neighboring pixels that are not part of the same object. Second, the algorithms are limited to the resolution of the image and cannot account for sub-pixel detail. Also, temporal coherence can be an issue and the shower-door effect, where the lines appear to be drawn on the viewing plane and not on the object (Meier 1996), must be managed. Finally, stylization can be difficult as feature lines are not represented with geometry.

Object-based methods typically use second- and third-order surface properties to extract feature lines directly from a polygonal model in world-space. Suggestive contours (DeCarlo et al. 2003), apparent ridges (Judd, Durand, & Adelson 2007), and demarcating curves (Kolomenkin, Shimshoni, & Tal 2008) are examples of object-based techniques. These algorithms can be divided into two groups: view-dependent and view-independent. View-dependent methods include the viewing direction when extracting feature lines, view-independent methods do not. Both groups of techniques, however, rely on some method for estimating curvature on a mesh.

Occluding, or silhouette, contours require normals (first-order structure), apparent ridges require curvature (second-order structure), and suggestive contours and demarcating curves require the derivative of maximum and minimum

(i.e. principal) curvatures (third-order structure).

## 2.4 Vertex Blended Animation

Vertex blended animation, also called vertex skinning, is an animation technique where the vertices of a model are deformed each frame by a set of weighted transformation matrices. Each vertex is assigned one or more bones along with a weight for each bone assignment. For each frame, the vertices are transformed using the weighted transformation matrices of the assigned bones.

This technique, often called linear blend skinning, is the most common method used. Other techniques have been proposed, however, such as dual-quaternion blending (Kavan et al. 2008). I have implemented linear blend skinning to demonstrate the effectiveness of our algorithm, but do not make any specific contribution to the area of vertex blended animation, and refer the reader to existing excellent surveys (Akenine-Möller, Haines, & Hoffman 2008; Jacka et al. 2007) for further discussion of vertex blended animation.

## 2.5 Isosurface Reconstruction

Surface reconstruction is one of the most frequently used methods to analyze and visualize volumetric data. Marching cubes (Lorensen & Cline 1987) is the most widely used algorithm for computing a triangular surface or model from volumetric data. Treece et al. (1999) use a variation of marching cubes, marching tetrahedra, that is easier to implement and handles non-gridded data. Geiss (2007) introduces a marching cubes implementation using the programmable graphics pipeline. To improve the speed of his implementation, he introduces a method for pooling vertices and creating an indexed triangle list. My algorithm does require shared vertices, however, Geiss' method is limited to a fixed voxel

size. In Section 3.5, I introduce a CUDA implementation of marching cubes that uses a hash map to fuse vertices.

## 2.6 Graphics Hardware

Graphics hardware has evolved considerably over the last decade. Modern GPUs are massively parallel programmable units. Below, I describe the architecture of modern GPUs and then discuss their programmability.

### 2.6.1 Architecture

Graphics processing units were initially introduced as fixed-function hardware implementations of the graphics pipeline. Over the last decade, different stages of the pipeline have become programmable (Section 2.6.2). As more stages became programmable, GPU architectures evolved into a more general Single-Instruction Multiple-Data (SIMD) (Flynn 1972) architecture, with a unified architecture implementing a “common-core” Application Programming Interface (API) (Blythe 2006).

The unified architecture of modern GPUs uses many small, lightweight vector processing units. The processing units are grouped into cores which share a small local memory store. Each processing unit also has access to a larger global

FIGURE 2.4: The modern programmable graphics pipeline. The shaded stages are programmable, while the non-shaded stages are highly configurable.

memory. The programs (shaders) corresponding to the programmable stages of the pipeline are executed on the processing units.

To hide memory latency, a hardware scheduler attempts to maximize the utilization of the processors by scheduling many independent programs on the processing units and using very fast context switching to switch between the programs. The combination of hardware scheduling and fast context switching allows a GPU to reassign processors and shuffle data around very efficiently, especially compared to large-scale computing clusters such as the Roadrunner supercomputer (Barker et al. 2008).

### **2.6.2 Programmability**

Olano and Lastra (1998) introduced the first system capable of real-time procedural shading in hardware. Lindholm et al. (2001) presented the first programmable vertex shader on a GPU. Proudfoot et al. (2001) introduced programmable vertex and pixel shader stages. Blythe (2006) added an additional stage to the programmable pipeline: the geometry shader stage. This stage operates on entire primitives and can access every vertex of an input primitive.

GPUs are ideally suited to executing data-parallel algorithms. Data-parallel algorithms execute identical units of work (programs) over large sets of data. The algorithms can be parallelized for efficiency when the work units are independent and are able to run on small divisions on the data. One critical aspect of designing parallel algorithms is identifying the units of work and determining how they will interact via communication and synchronization. A second critical aspect is analyzing the data access patterns of the programs and ensuring data locality to the processing units. A final factor is scheduling the programs to run on hardware and moving the data to where the programs will execute (Almasi & Gottlieb 1994).

In a cluster supercomputer, parallel processes run simultaneously and communicate through shared memory or message passing. Since the GPU uses process scheduling to increase efficiency (Section 2.6.1), two processes that want to communicate may not even be running at the same time. To allow communication, the GPU programmer introduces barriers defined by passes (or kernels). Results written by one kernel (or pass) can be randomly accessed in the next. Thus, the defining feature of parallel algorithm design for the GPU is not as much data assignment to processors as the selection of passes/kernels and synchronization points.

## PARALLEL ALGORITHM

My algorithm is based on the CPU algorithm by Rusinkiewicz (2004). In his algorithm, Rusinkiewicz creates a set of linear constraints to solve for curvature (Equation 2.7) over a single face. The constraints use the differences between normals along edges and are solved using least squares. To find the curvature at a vertex, the per-face curvatures of each adjacent face are averaged together.

The algorithm is composed of several iterative steps that can be grouped based on the type of input to each step: either per-face or per-vertex. While each step builds on the computation from the previous step, within each step the computation is independent over each subdivision on the input. That is, a per-face step works on a single face and a per-vertex step works on a single vertex. My parallel algorithm exploits this independence of computation to parallelize the work within each step.

Table 3.1 summarizes the iterative steps listed below, grouping them based on the type of input to each step.

1. **Normals.** Normals at each vertex are computed by averaging the per-face normals of the one-ring.
2. **Areas.** A weighting is calculated to determine how much a face contributes to each of the three vertices.
3. **Initial Coordinates.** An orthonormal basis is generated at each vertex. This basis is used to transform the curvature tensor at each vertex.
4. **Curvature Tensor.** An over-specified linear system for the tensor of a face

Input	Operation	Output	One-Ring
Face	Normals	Vector	Averaged
	Areas	Scalar	Summed
	Initial Coordinates	2 Vectors	No
	Curvature Tensor	3 Scalar Values	Averaged
Vertex	Curvature Differential	4 Scalar Values	Averaged
	Principal Directions	2 Vectors &	No
	& Principal Curvatures	2 Scalar Values	

TABLE 3.1: Operations that can be performed in parallel grouped by their input. The output is listed as well as whether it should be averaged or summed across the one-ring neighborhood of a vertex.

is created from the differences of normals along the edges of the face and solved using  $LDL^T$  decomposition and least squares fit. The tensor is rotated into a local coordinate system at each vertex using the orthonormal basis and weighted by the area of the vertex. These weighted tensors at each vertex are summed across the one-ring to compute the averaged curvature tensor at each vertex.

5. **Principal Directions.** The Jacobi method is then used to diagonalize the curvature tensor at each vertex and approximate eigenvalues and eigenvectors and thus compute principal curvatures and directions.
6. **Principal Curvatures Differential.** The principal curvatures at each vertex are used to find the differential of principal curvatures by solving a set of linear constraints per face and averaging across the one-ring.

### 3.1 Complexity Analysis

The steps described above are all composed of mathematical operations, loading and storing values to memory locations, and fixed-length loops (either three or four iterations). Thus the CPU algorithm is linear in the size of the input. Five of

<b>Model</b>	<b>Average Valence</b>
torus	6.0000
horse	5.9932
camel	6.0055
elephant	5.9997
elephant (HQ)	5.9839
heptoroid	6.0009

TABLE 3.2: Average valence of the models.

the six steps operate on faces, while the sixth step operates on vertices, so the input size depends on the step.

Given a model with  $n$  vertices, the number of faces,  $f$  can be approximated:

$$(3.1) \quad f \approx \frac{n * V}{3},$$

where  $V$  is the average valence of the model. The valence of a vertex is the number of edges connected to the vertex, so the average valence of a model is the sum of the valences at each vertex divided by the total number of vertices in the model. Table 3.2 lists the average valence for the set of models that I describe in Chapter 4.

In Equation 3.1, each vertex is, on average, connected to  $V$  faces. Each face, however, is shared by three vertices and this fact is accounted for by the division.

Since the steps in Table 3.1 are iterative, the running time,  $T(n)$ , of the CPU algorithm on a model with  $n$  vertices and constant average valence  $V$  is the sum of the running times of each step:

$$(3.2) \quad \begin{aligned} T(n) &= O(f) + O(f) + O(f) + O(f) + O(f) + O(n) \\ &= 5 * O\left(\frac{n * V}{3}\right) + O(n) \\ &= O(n) \end{aligned}$$

### 3.2 Parallel Considerations

As discussed in Section 2.6, data locality is critical to algorithm efficiency and hardware utilization. The steps discussed above all use only the local data of a face or vertex. Thus, parallel implementations of each step should be efficient as the memory access pattern of each step is localized.

In addition to grouping the steps based on the type of input, Table 3.1 lists the type of output and whether the output must be averaged or summed across the one-ring neighborhood of a vertex for each step. Except for the **Principal Directions & Principal Values** step, the output from each step will fit into a four-component vector. Again, this means parallel implementations of each step should be efficient, as GPUs are optimized for writing to buffers of four-component vectors, and each step can write to a single output buffer.

The **Principal Directions & Principal Values** step outputs two vectors, one for each principal direction of curvature, and two scalar values, one for each principal curvature. The scalars can be combined with their respective vectors and thus this step will require two output buffers.

### 3.3 Computational Primitives

Based on Table 3.1 and the previous discussion, I define two computational primitives to implement the parallel algorithm:

1. A per-vertex primitive that takes a single vertex as input, and outputs a computation at the vertex.
2. A per-face primitive that takes a single face (composed of three vertices) as input, and outputs a computation at each vertex of the face that will be averaged or summed across the one-ring neighborhood.

In a parallel algorithm, the data parallel threads will be distributed across both processors and time. Data written by one thread that will be read in another thread must force a barrier for all threads to complete. In my algorithm, the per-vertex computations are independent and thus need no barrier between other threads. However, since the per-face computations are averaged or summed across multiple threads, a barrier is required.

### 3.4 Primitive Implementation

There are two possibilities for implementing the computational primitives: the graphics pipeline, using shaders, or the general purpose APIs such as Compute Unified Device Architecture (CUDA) (NVIDIA 2009). Functionally, both choices are equivalent, they each execute on the same hardware. The primary differences in the approaches relative to this work are more flexible shared memory access in CUDA and special purpose hardware for blending in the graphics pipeline.

The algorithm needs to sum across several threads, which could be accomplished with a CUDA atomic add or graphics pipeline blending. In either case a pass or kernel barrier must be introduced before using the results. The writes to the output buffers cannot be constrained to a single thread block, so a CUDA implementation would need a full kernel synchronization point, not just the lighter-weight syncthreads barrier. In contrast, GPUs have special hardware for blending to output buffers (render targets) with dedicated Arithmetic Logic Units (ALUs), optimized for throughput.

Curvature estimation is a geometric problem, treating it as such, i.e. using the geometric pipeline, allows use of the more efficient blending hardware to synchronize access instead of atomic operations accompanied by an immediate kernel end. Additionally, when the geometry already exists in a format that the graphics pipeline expects (i.e. indexed vertex buffers), using the pipeline

FIGURE 3.1: The left is a triangle containing vertex  $v_2$  with adjacent vertices. The right is a one-ring neighborhood of faces around vertex  $v_2$ . Notice that adjacency information does not allow access to vertices  $v_6$  and  $v_7$  in the one-ring.

automatically handles setting up the geometry for the shader instances.

There are cases, however, when a general purpose API is the better choice. I describe in Section 3.5 a marching cubes CUDA implementation. In that situation, there is no benefit to using the geometric pipeline and, in fact, I implement a hash map to fuse vertices while extracting the isosurface using the atomic operations in CUDA.

Given the choice of the graphics pipeline, the per-vertex primitive is implemented in a vertex shader and the per-face primitive is implemented in a geometry shader that outputs a set of point primitives for each vertex of the face. The computation across the one-ring neighborhood of the per-face computation creates a complication when using geometry shaders. As Figure 3.1 illustrates, the adjacency information provided as input to a geometry shader does not provide access to the one-ring of a vertex. However, since the operation across the one-ring is either averaged or summed, the computation can be accomplished by using additive blending into a render target.

Figure 3.2 shows how each vertex in a mesh is mapped to a single pixel in a render target. Inside a geometry shader, the per-face computation is output as a point primitive. The point primitives are then written to a render target, which is a buffer of GPU memory, in a pixel shader program using additive blending,

FIGURE 3.2: The contribution of the one-ring neighborhood of a vertex is averaged by blending into a single pixel of a render target. A single vertex with the one-ring of faces is indicated by the dashed circle. The same vertex from each face is mapped as a point primitive to a single pixel of a render target. The blue lines show a complete one-ring, while the red and green lines show how other vertices could be mapped.

where the current value in the shader is added to the existing value in the target. Using this technique, the algorithm can easily average or sum values of the one-ring neighborhood around a vertex. While this mapping technique requires input meshes with fused vertices, in practice, fusing vertices is not a difficult task. In Section 3.5 I discuss fusing vertices when extracting isosurfaces.

### 3.5 Parallel Instances

Figure 3.3 is a flowchart of the parallel algorithm, where the outer grey outline surrounds the actual algorithm. Since each step of the algorithm described in Section 3 builds on the computation from the previous step, synchronization points between each step of the algorithm are necessary. Render passes are natural synchronization points and since the one-ring computation uses additive blending to a render target, the synchronization barrier between each step is a pass through the pipeline.

Each pass of the parallel algorithm is shown on the left with the correspond-

ing output render targets on the right. Each render target is connected to the subsequent passes that use the buffer as input. Each pass is an instance of one of the computational primitives described in Section 3.3. In Figure 3.3, the passes with square corners average or sum the output over the one-ring neighborhood, while the passes with round corners do not.

To demonstrate the algorithm, I have implemented a GPU-based isosurface extraction system and a vertex-blending animation system, both of which use curvature to extract and stroke occluding and suggestive contours on input data.

To support the two types of input: volumetric datasets and skinned animations or static models, I have two initial passes that either compute an isosurface for a volumetric dataset (**Isosurface**) or animate the vertices using vertex skinning (**Skin**). If a static model, i.e. a triangular mesh with no animation, is input, the **Skin** pass is still used.

After transforming the input, the iterative steps of the algorithm are run. Once the algorithm has completed, I use the curvature results to extract and stroke contours on the input data. To ensure high-quality contour stroking, I compute a super-sampled depth buffer in the **Depth** pass.

I describe these steps as well as each step of the algorithm below.

### 3.5.1 Isosurface

To demonstrate occluding and suggestive contours on volumetric datasets, I first compute an isosurface from the input data. This pass is a standard CUDA marching cubes implementation to compute an isosurface over the volume. However, since the parallel curvature algorithm requires shared vertices to map the one-ring around each vertex (Section 3.4), I modify the algorithm to output an indexed, fused triangle list.

After classifying the voxels and determining how many vertices are needed

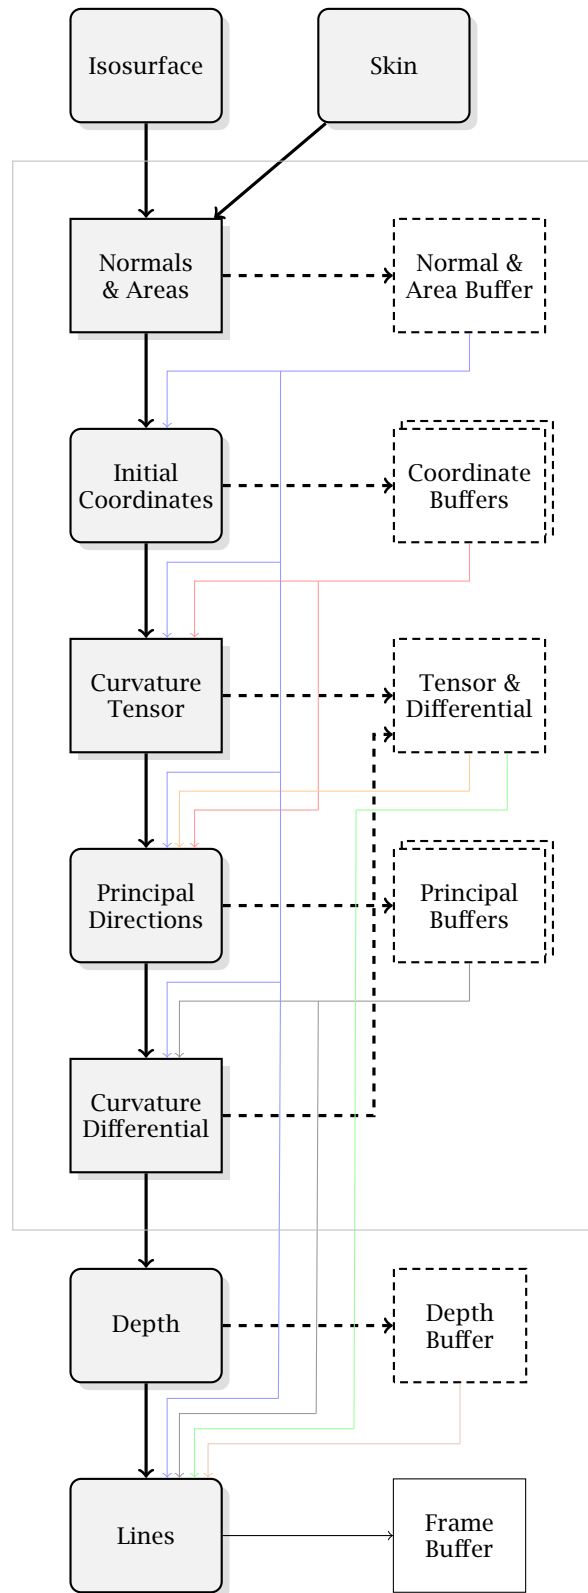

FIGURE 3.3: Flowchart of the parallel algorithm. The outer grey outline encloses the main algorithm. See Section 3.5 for further discussion.

for each active voxel, two sequential kernels are run: a triangle kernel and an index kernel. The triangle kernel generates the vertex buffer along with a “full” index buffer, where every vertex is separately indexed and the index kernel generates the final index buffer, containing only shared indices.

Each instance of the triangle kernel will create anywhere from zero to twelve vertices. When a vertex is created, three arrays are filled in: the vertex buffer with the actual vertex, the “full” index buffer, and a hash code buffer with the hash code of the vertex. Using radix sort (Satish, Harris, & Garland 2009), I sort the hash code and index buffers as key/value pairs.

The index kernel then re-creates the vertices and hash codes and, for each vertex, uses binary search to locate the first index of the current vertex in the vertex buffer. Since there may be duplicate keys, once the binary search terminates, if a match was found, the search algorithm traverses backwards in the key buffer until the first hash code is located. To resolve collisions in the hash function, after locating a match, the kernel traverses forwards in the key buffer, comparing the corresponding value in the vertex buffer with the current vertex. Once the kernel has located the first vertex in the vertex buffer that matches the current vertex, it writes the corresponding index to an final, fused index buffer.

### 3.5.2 Skin

To demonstrate occluding and suggestive contours on skinned animations or static models, I use a vertex shader to skin each vertex based on the current set of keyframe matrices as described in Section 2.4. In the case of a static, or non-animated, model, the output vertex position is the same as the input vertex position. The deformed vertices are written to a new buffer in GPU memory using the stream out mechanism (Blythe 2006).

### 3.5.3 Normals & Areas

The curvature algorithm requires high quality normals at each vertex in the mesh. Since my input data could be changing each frame, this pass re-calculates a normal and an area for each vertex of a face in a geometry shader. To start, the geometry shader calculates a face normal for each triangle in the mesh. The normal at a vertex is the weighted average of face normals across the one-ring of the vertex. Like Rusinkiewicz (2004), the area at a vertex is the Voronoi area described by Meyer et al. (2003) and is used in later passes to weight the contribution of each face to the vertices that compose the face. Using the one-ring computation technique described in Section 3.3, the face normals of the one-ring at a vertex are averaged together and the areas of the one-ring are summed.

Since the normal is a three-component floating point vector and the area is a floating point scalar value, both the normal vector and area scalar are packed into a single four-channel render target.

### 3.5.4 Initial Coordinates

An orthonormal basis is required at each vertex to transform the curvature tensor of a face into a local coordinate system. The basis is computed using a geometry shader and each vector is written to a separate four-channel render target.

While it would seem that the basis could be created as needed in any later passes, each vertex needs a single basis so that all of the per-face curvature tensor transformations happen in the same coordinate system. If the bases were computed on the fly, then each face attached to the same vertex would use a different basis based on that face. Thus, this separate pass computes a single, constant basis for each vertex based on a single face.

### 3.5.5 Curvature Tensor

Before computing principal directions and principal curvatures, my algorithm must estimate the curvature tensor at each vertex in the mesh. I use a geometry shader to compute the curvature tensor at each face (Equation 2.7). For each edge, the shader computes the differences of normals along the edges. A linear system for the tensor is created from those differences and a solution is found using least squares. Using the one-ring computation technique, the weighted tensor at each face is averaged across the one-ring to compute the curvature tensor at a vertex. The tensor is three floating point values and is stored in a four-channel render target.

### 3.5.6 Principal Directions

I use a vertex shader to compute the minimum and maximum curvatures and principal directions at each vertex. Since this pass only needs to execute over a single vertex, no geometry shader is used and no blending is used in the pixel shader. The minimum curvature and principal direction are packed into one four-channel buffer and a second four-channel buffer is used for maximum curvature and principal direction.

Figure 3.4 shows principal curvatures and direction of minimum curvature

FIGURE 3.4: Two close-up frames of a vertex-blended animation showing principal curvatures and principal directions of minimum curvature (blue lines).

(blue lines) from this pass in two consecutive frames of an animation. In the first frame, the large red area is where the shin is bent such that the surface is curving away from the surface normal at each point. As the shin straightens in the second frame, the red area shrinks and is replaced by portions of green, where the surface is curving away from the surface normal in one direction and curving towards the surface normal in another direction at each point. Coloring principal curvatures is discussed further in Section 4.3.

### 3.5.7 Curvature Differential

Suggestive contours (DeCarlo et al. 2003) and demarcating curves (Kolomenkin, Shimshoni, & Tal 2008) both require the derivatives of principal curvatures. Not all curvature estimation algorithms can generate these derivatives, however Rusinkiewicz's method is able to estimate them and thus my parallel algorithm is able to estimate them as well.

I use a geometry shader to compute the derivative of principal curvatures using the same process as the Curvature Tensor pass. The derivative is essentially a third-order property, incorporating information from a two-ring around the vertex (i.e. a one-ring of data computed on a one-ring around a vertex). Thus, the variation of principal curvatures along the edge of a face is used instead of using the variation of normals. These per-face differentials are averaged over the one-ring of faces. The derivative of principal curvatures is represented with a four-component floating point value. The output of the Curvature Tensor pass is no longer needed at this point, so the Tensor & Differential four-channel render target is reused for this pass.

### 3.6 Depth

To improve the quality of the stroke contours, I create a super-sampled depth buffer for high-quality visibility testing in this pass. This depth buffer is used only for line drawing and does not affect the curvature estimation. All curvature computations happen at the polygon or vertex level in object space and the quality of the estimation is not affected by any image or depth buffer resolution.

### 3.7 Drawing Lines

The final goal of my system is to extract and stroke occluding and suggestive contours on the input data (either volumetric datasets or animated models). Once the curvature algorithm has run, the Principal Buffers and Tensor & Differential Buffer are used, along with a super-sampled Depth Buffer, to extract feature lines on the model. Lines are extracted in segments that are created per-face in a geometry shader program. Currently my system extracts occluding and suggestive contours. Line segments are created in the geometry program in one of two ways: either as line primitives that are rasterized by the hardware, or as triangle strips that can then be textured for stylized strokes.

When extracting line segments in the geometry shader, a global parameterization cannot be applied. Since the geometry program extracts only a single line segment across a face, the program has no knowledge of where in the feature line the segment is or how long the segment is. Also, since the line segments reside on the GPU, globally traversing the set of segments is extremely inefficient. Thus, a stylization of the lines must not rely on any parameterization or global access to the line, but can use 3D positions and procedural noise methods to add stylization much like Johnston's woodblock shader (2000) or Freudenberg's stroke textures (2002).

## RESULTS

I discuss three types of results: performance, error, and visualization. Section 4.1 shows the actual performance of my GPU algorithm as well as a speedup comparison to a baseline CPU algorithm. Section 4.2 compares the absolute error of my GPU algorithm to a baseline CPU algorithm. Section 4.3 describes the methods used to visualize the curvature results.

#### 4.1 Performance

Tables 4.1, 4.2, 4.3, 4.4 along with Figure 4.1 show that my parallel algorithm achieves real-time performance for small- to medium-sized models, even on an older-generation consumer GPU. Results are shown for two different NVIDIA

FIGURE 4.1: Frame times and relative speedup for the non-animated models at  $1280 \times 1024$  resolution. The results are for just curvature estimation (no line drawing). Red is a multi-threaded CPU algorithm, blue is an NVIDIA GeForce 9800GT, and green is an NVIDIA Quadro FX5800.

GPUs, an older-generation consumer-oriented card (GeForce 9800GT with 512MB of RAM) and a high-end, workstation-class card (Quadro FX5800 with 4GB of RAM). For these results, small-sized models have less than 50,000 vertices and medium-sized models have between 50,000 and 300,000 vertices.

To benchmark the algorithm, I took an existing CPU algorithm and threaded it to run in parallel. The CPU algorithm was run on a Core2 Quad Q8200 workstation with 8GB of RAM and each core running at 2.33GHz. The Intel Threading Building Blocks (TBB) (Intel 2010) library provides a number of multi-threaded constructs, one of which is a `parallel_for`. The `parallel_for` construct takes a function and a range describing the data set that will be operated on. TBB then divides the work among a number of threads and executes the specified function on each thread over the subset of data. By default, TBB creates a number of threads equal to the number of processors (or cores) and I used this default to execute each step of the CPU algorithm over the four cores of the workstation. To synchronize thread access to shared data, I used a `concurrent_vector`, also part of TBB, to store the data set. After trying several methods, I found the combination of the TBB `parallel_for` and `concurrent_vector` to be the fastest.

The (x) columns show the relative speedup over the CPU algorithm.

Each line of Table 4.1 lists the number of vertices and faces and the memory usage of the algorithm in megabytes as well as the frame times for the animations and models on the CPU. The memory usage is broken out for just the render targets and geometry buffers as well as the total memory used for each model. Where possible, output buffers were reused to conserve memory. The total memory figure includes the super-sampled depth buffer and other shared overhead which total 64 MB. The super-sampled depth buffer dominates this overhead: at a resolution of  $1280 \times 1024$ , a 3x super-sampled depth buffer

TABLE 4.4: Frame times for different volumes at  $1280 \times 1024$  resolution on the NVIDIA Quadro FX5800. **I-V** is the iso value of the surface and **E-T** is the elapsed time to extract the surface. **Lines** refers to drawing non-textured line primitives. **Algorithm** refers to just the algorithm (no line drawing).

( $3840 \times 3072$  samples) uses 47 MB. Since current GPUs have at least 512MB of RAM, even the heptoroid model fits within the memory of a current GPU.

Each line of Tables 4.2 and 4.3 lists the frame times for the animations and models on the GeForce 9800GT and the Quadro FX5800 respectively. The **Procedural Lines** column lists the frame time in milliseconds for using procedurally generated line textures. The **Basic Lines** column lists the frame time in milliseconds for using simple line primitives. The **Algorithm Only** column lists the frame time in milliseconds for running just the algorithm along with the speedup achieved over the benchmark CPU algorithm (the (x) column).

The top three entries of Tables 4.1, 4.2, and 4.3 are small- to medium-sized animated models, while the middle three entries are the same models without the animation. Comparing the animated results with the corresponding non-animated results, the frame times are very close, most within 0.1 milliseconds. The additional step of skinning models for animation adds very little runtime to the algorithm. The bottom two entries are large, high-quality models with no animation.

The times on the NVIDIA Quadro FX5800 indicate that the algorithm scales well with increasing hardware resources. Even on the largest model, the hep-

Attribute	FX5800 Max Error	9800GT Max Error	Attribute	FX5800 Max Error	9800GT Max Error
Max Dir	$1.406 \times 10^{-6}$	$4.34 \times 10^{-7}$	Deriv 1	$9.512 \times 10^{-5}$	$7.07 \times 10^{-5}$
Max Curv	$7.391 \times 10^{-6}$	$3.34 \times 10^{-6}$	Deriv 2	$3.198 \times 10^{-5}$	$3.47 \times 10^{-5}$
Min Dir	$1.281 \times 10^{-6}$	$4.17 \times 10^{-7}$	Deriv 3	$2.933 \times 10^{-5}$	$2.67 \times 10^{-5}$
Min Curv	$4.053 \times 10^{-6}$	$2.50 \times 10^{-6}$	Deriv 4	$4.163 \times 10^{-5}$	$4.13 \times 10^{-5}$
Gauss Crv	$1.574 \times 10^{-5}$	$1.10 \times 10^{-5}$	Mean Crv	$5.007 \times 10^{-6}$	$1.91 \times 10^{-6}$

TABLE 4.5: Maximum absolute error in the curvature attributes over the torus.

toroid with  $\sim 286\text{K}$  vertices and  $\sim 573\text{K}$  faces, the algorithm runs in 41.9 milliseconds or 23 frames per second.

Figure 4.1 plots frame times against vertex count on the left for the non-animated models at  $1280 \times 1024$  resolution. The frame times are just for the algorithm (no line drawing). The red line is a multi-threaded CPU algorithm. The blue line is an NVIDIA GeForce 9800GT. The green line is an NVIDIA Quadro FX5800. This graph clearly illustrates the speedup achieved by my parallel GPU algorithm over the multi-threaded CPU algorithm. The right of the figure shows that the relative speedup achieved over the CPU algorithm remains roughly the same as the number of vertices increases.

Each line of Table 4.4 lists the volume data set, the number of vertices that were generated given the specific iso value, along with the amount of time in milliseconds it took to extract the surface and estimate curvature over the surface. Even for the largest surface, which had  $\sim 1.559\text{B}$  vertices, the curvature algorithm still only took 32.1 milliseconds to estimate curvature over the entire surface.

## 4.2 Error

To check the accuracy of my GPU algorithm, I compare the results of my algorithm to a baseline CPU estimation algorithm on the torus model. Table 4.5 lists the maximum absolute error over the entire torus mesh for both NVIDIA GPUs.

Rusinkiewicz (2004) compares the robustness and accuracy of his CPU al-

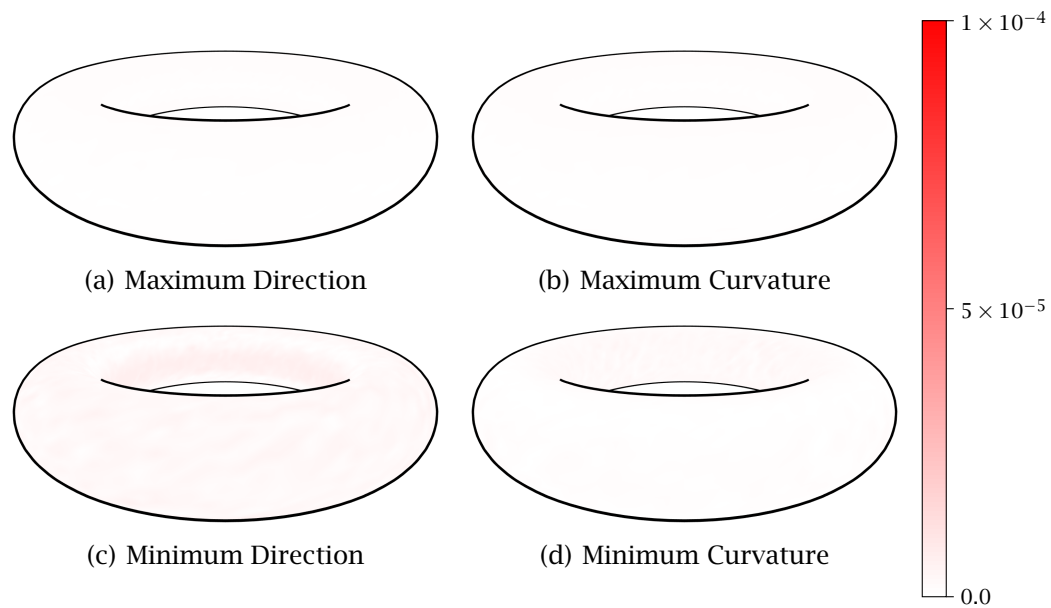

FIGURE 4.2: Scaled absolute error in the principal directions and principal curvatures on the Quadro FX5800 compared to a CPU estimation ground truth.

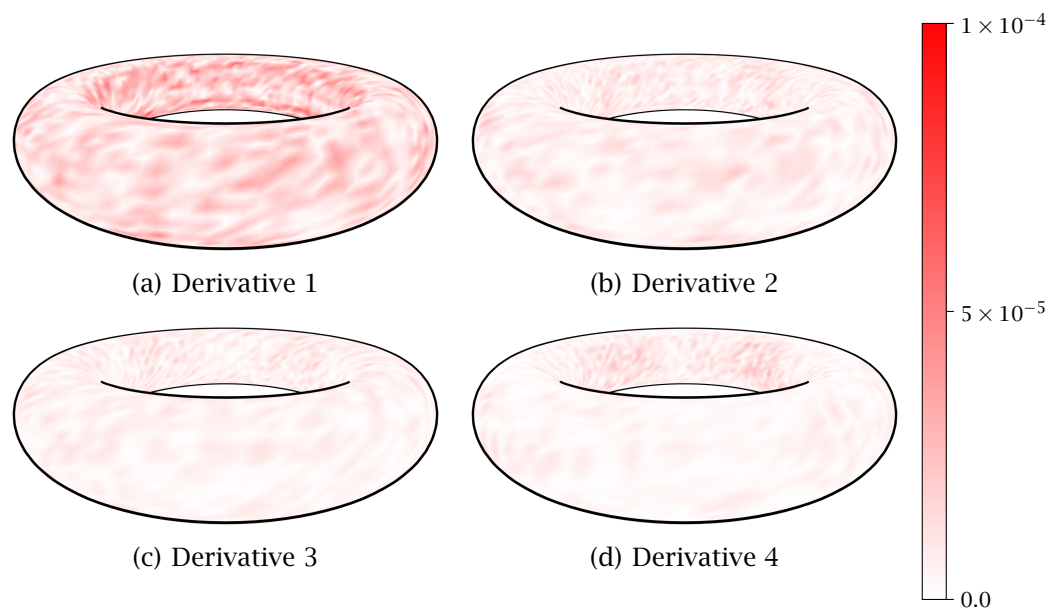

FIGURE 4.3: Scaled absolute error in the estimated derivative of principal curvature on the Quadro FX5800 compared to a CPU estimation ground truth.

FIGURE 4.4: Scaled absolute error in the estimated Gauss and Mean Curvatures on the Quadro FX5800 compared to a CPU estimation ground truth.

gorithm to other estimation algorithms. Since my algorithm is a parallel implementation of his CPU algorithm, the error I report here is the error introduced by the GPU implementation. As Table 4.5 shows, the absolute errors are very small. To visualize where the errors are occurring, I have scaled the absolute error up and mapped the error at each vertex to the torus mesh.

Figure 4.2 shows the scaled error for both principal directions (Figures 4.2(a) and 4.2(c)) and principal curvatures (Figures 4.2(b) and 4.2(d)). Figures 4.3(a), 4.3(b), 4.3(c), and 4.3(d) show the scaled error for the four scalar values that describe the derivative of principal curvatures. Figures 4.4(a) and 4.4(b) show the scaled error of the estimated Gauss and Mean Curvature respectively.

### 4.3 Visualization

Coloring values of principal curvature ( $k_1$  and  $k_2$ ) helps to visually understand how a surface curves at specific points. There are four interesting points (Gray, Abbena, & Salamon 2006):

- **Elliptic** where the surface is completely curving in the same direction, i.e. either towards the surface normal at the point or away from the surface normal.

- **Hyperbolic** where the surface curves both towards the surface normal in one direction at the point and away from the surface normal.
- **Parabolic** where the surface is curved in one direction and flat in another direction. When a surface is elliptic and hyperbolic, the two areas will be separated by a parabolic area.
- **Planar** where the surface is not curving at all (i.e. flat).

These points can be classified by the values of principal curvature:

- **Elliptic:**  $k_1$  and  $k_2$  have the same sign
- **Hyperbolic:**  $k_1$  and  $k_2$  have the opposite sign
- **Parabolic:** one of either  $k_1$  and  $k_2$  is zero
- **Planar:** both  $k_1$  and  $k_2$  are zero

A good coloring of principal curvatures would allow distinguishing these four types of points. Figure 4.5 is a coloring that assigns the following colors to the four points:

- **Elliptic:** red or blue, where red indicates the surface is curving away from the surface normal at the point and blue indicates the surface is curving towards the surface normal
- **Hyperbolic:** green
- **Parabolic:** yellow or cyan, where yellow indicates this parabolic region borders a red elliptic region and a hyperbolic region and cyan indicates this parabolic region borders a blue elliptic region and a hyperbolic region.
- **Planar:** white

FIGURE 4.5: A coloring of principal curvatures as described in Section 4.3.

FIGURE 4.6: The bucky ball volume with two different iso values and principal curvatures. The marching cubes algorithm takes 40 ms to reconstruct the surface, and the curvature algorithm takes 1.3 ms to estimate curvature.

Figure 4.6 shows occluding and suggestive contours on the bucky ball volume. The left and center pictures are a computed surface with one iso value and the right picture is a computed surface from a different iso value. The coloring of principal curvatures is applied in the middle picture. The red areas correspond to the elliptic points, where the surface is curving away from the surface normal. There are the “knobs” on the bucky ball. The green areas are hyperbolic points, where the surface is curving towards the surface normal in the direction of the elliptic points, but is still curving away from the surface normal in the perpendicular direction. The red and green areas are separated by a thin yellow region, where the points are parabolic. The parabolic points are flat in the direc-

FIGURE 4.7: The heptoroid model with 286,678 vertices. The top left and middle images show occluding and suggestive contours with lambertian shading, while the bottom left and right images show values of principal curvature.

tion of the elliptic points, but are still curving away from the surface normal in the perpendicular direction.

Figure 4.7 shows the heptoroid model with 286,678 vertices with my algorithm computing curvature in 41.9 milliseconds on the NVIDIA Quadro FX5800. Figures 4.8 and 4.9 are representative animated models used in games, with 21,887 vertices and 8,431 vertices respectively. My algorithm computes curvature every frame in 6.3 and 2.9 milliseconds respectively on the NVIDIA GeForce 9800GT. The animated models are from the Skinning Mesh Animations data (James & Twigg 2009).

Figure 4.10 is a model with 78,792 vertices which my algorithm computes curvature in 12.5 milliseconds on the NVIDIA Quadro FX5800. Figure 4.11 shows the bucky ball volume with tone shading. The extracted isosurface of the bucky ball has 43,524 vertices and my algorithm computes curvature in 1.3 milliseconds on this surface. Finally, Figure 4.12 is an isosurface extracted from the orange volume data set with 1,558,788 vertices. On the NVIDIA Quadro FX5800, my algorithm computes curvature in 32.1 milliseconds on this surface. The volumes are from Stefan Röttger (2010).

FIGURE 4.8: A sequence of frames from the camel model. The middle frame shows principal directions and the last frame shows principal values of curvatures.

FIGURE 4.9: The animated horse model. The first two pictures show just the principal curvatures. The last two pictures show the principal directions of minimum (blue lines) and maximum (brown lines) curvature.

FIGURE 4.10: Principal curvatures on the high-quality elephant model.

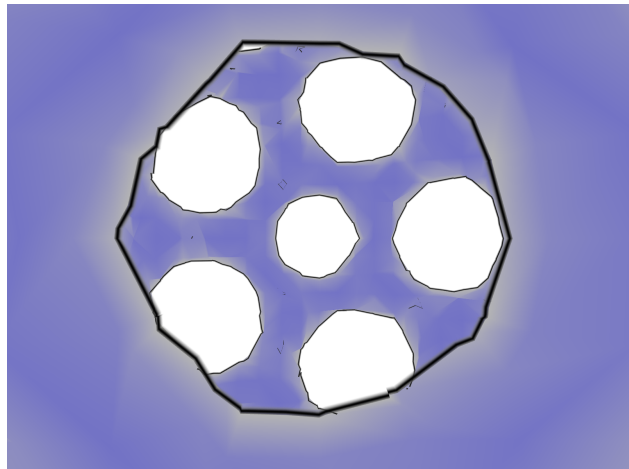

FIGURE 4.11: Looking into an extracted surface of the bucky ball volume with tone shading.

FIGURE 4.12: The orange volume with over 1.5B vertices. Curvature is estimated in 32.1 ms (31 fps) on this surface that is computed in 928 ms.

## CONCLUSIONS AND FUTURE WORK

Surface curvature is used in a number of areas in computer graphics and must be estimated on discrete triangular meshes. More computational work is being done directly on the GPU and it is increasingly common for object geometry to only exist in GPU memory. Existing CPU algorithms for curvature estimation, which would require GPU-resident geometry to be transferred to CPU memory, are cost prohibitive and limit the performance of interactive applications.

I have presented a GPU algorithm for estimating curvature in real-time on arbitrary triangular meshes residing in GPU memory along with results showing real-time performance in a vertex-skinned animation and non-photorealistic line drawing system.

Including additional types of contours, such as apparent ridges (Judd, Durand, & Adelson 2007), is one possible extension of our work. Because the algorithm can output line primitives from the geometry shader, it can co-exist nicely with the algorithm introduced by Cole et al. (2009) for line visibility and stylization.
